

Same four door events, three statistics — the separation margin differs by 2×

Each dot is one trial ($n=2$ per condition); the bar spans the two, the green band and arrow mark the gap between the loudest close and the quietest slam. All three statistics order the conditions correctly here — but peak window RMS leaves a $1.4\times$ margin where the energy integral leaves $2.7\times$. At $n=2$ none of this is significant: the smallest p an exact test can return with two trials per condition is 0.167. Margin is what survives more trials, which is why the protocol now fixes $n=6$.
